COVID-19 Results Briefing

Global

October 15, 2021

This document contains summary information on the latest projections from the IHME model on COVID-19 globally. The model was run on October 13, 2021, with data through October 11, 2021.

At the global level, the pandemic continues to decline, reaching 3.3 million infections, which is the lowest level of transmission since May of 2020. While the global pandemic is in a period of decline, transmission is still increasing in various clusters of countries including those in Central and Eastern Europe, some US states, Chile, some states in Brazil, Cameroon, Gabon, Somalia, and in Australasia. Vaccination rates continue to increase, with large parts of South America and South Asia now reaching over 50% with a single dose. First-dose vaccination in all countries of Africa (except Morocco) remains at levels below 30% and most are below 10%. We expect that the nadir of transmission will be about now. Despite vaccination increases, the combination of declining mask use, increased mobility, and seasonality is likely to lead to increases in transmission in many parts of the Northern Hemisphere. These increases will probably be enough to reverse the global decline. Global infections, however, should remain below 5 million a day through the end of the year. With higher levels of vaccination, global deaths should remain below 7,500 at the end of the year. A huge range of trajectories, however, are possible given that relatively small increases in mobility and faster declines in mask use can tip many more countries into more rapid increases in transmission. We are generally observing that governments are increasingly reluctant to impose social distancing mandates this far into the pandemic. The main strategies for reducing the more than 600,000 deaths expected between now and the end of the year are expanding vaccination coverage through increasing supply of vaccination in low resource settings through vaccine donations, increasing immunity in the most vulnerable through vaccine boosters in countries expecting winter surges, and encouraging seasonal mask use. In most Northern Hemisphere countries, we expect that this winter hospital systems will face the combined impact of a moderate level of COVID-19 hospitalization and flu. Our reference scenario does not take into account waning natural or vaccine-derived immunity and thus may be optimistic. The emergence of a new variant with substantial immune escape could dramatically alter the trajectory of the pandemic in the world.

Current situation

- Estimated daily infections in the last week decreased to 3.3 million per day on average compared to 3.4 million the week before (Figure 1).

- Estimated daily hospital census in the last week (through October 11) decreased to 617,000 per day on average compared to 657,500 the week before.

- Daily reported cases in the last week decreased to 488,000 per day on average compared to 531,100 the week before (Figure 2).
Reported deaths due to COVID-19 in the last week decreased to 8,000 per day on average compared to 8,400 the week before (Figure 3).

Total deaths due to COVID-19 in the last week decreased to 15,400 per day on average compared to 16,500 the week before (Figure 3). Note that this week we have changed from reporting excess deaths related to the pandemic to reporting deaths directly related to COVID-19 infection. This makes COVID-19 the number 3 cause of death globally this week (Table 1). Estimated total daily deaths due to COVID-19 in the past week were 1.9 times larger than the reported number of deaths.

The daily rate of reported deaths due to COVID-19 is greater than 4 per million in 32 locations (Figure 4). These locations are nearly all in North America or Central and Eastern Europe.

The daily rate of total deaths due to COVID-19 is greater than 4 per million in 60 locations (Figure 4).

We estimate that 40% of people globally have been infected as of October 11 (Figure 6).

Effective R, computed using cases, hospitalizations, and deaths, is greater than 1 in 125 locations. (Figure 7). Key clusters of countries with increasing transmission are in South America, some US states, Central and Eastern Europe, West Africa, and Australasia.

The infection-detection rate globally was close to 12% on October 11 (Figure 8).

Based on the GISAID and various national databases, combined with our variant spread model, we estimate the current prevalence of variants of concern (Figure 9). The Delta variant is dominant in all regions, although other variants play a role in some South American countries.

Trends in drivers of transmission

Mobility last week was 2% lower than the pre-COVID-19 baseline (Figure 11). Mobility was near baseline (within 10%) in 136 locations. Mobility was lower than 30% of baseline in Cambodia, Lao People's Democratic Republic, Maldives, Myanmar, Seychelles, Sri Lanka, and Viet Nam.

As of October 11, in the COVID-19 Trends and Impact Survey, 57% of people self-report that they always wore a mask when leaving their home (Figure 13).

There were 163 diagnostic tests per 100,000 people on October 11 (Figure 15).

As of October 11, 41 locations have reached 70% or more of the population who have received at least one vaccine dose, and 20 locations have reached 70% or more of the population who are fully vaccinated (Figure 17). Vaccination coverage for one dose remains less than 20% in most of Africa (with the exception of Morocco), most of Central America, and parts of the Middle East.
Globally, 75.5% of the population that is 12 years and older say they would accept or would probably accept a vaccine for COVID-19. Note that vaccine acceptance is calculated using survey data from the 18+ population. The proportion of the 12 and over population who are open to receiving a COVID-19 vaccine ranges from 31% in Botswana to 100% in the United Arab Emirates (Figure 19).

In our current reference scenario, we expect that 4.1 billion people will be vaccinated with at least one dose by January 1 (Figure 20). We expect that 47% of the population will be fully vaccinated by January 1.

Based on the estimate of the population that have been infected with COVID-19 and vaccinated to date, combined with assumptions on protection against infection with the Delta variant provided by either natural infection, vaccination, or both, we estimate that 45% of the region is immune to the Delta variant. In our current reference scenario, we expect that by January 1, 51% of people will be immune to the Delta variant (Figure 21). These two calculations do not take into account waning of natural or vaccine-derived immunity.

**Projections**

- In our *reference scenario*, which represents what we think is most likely to happen, our model projects 5,893,000 cumulative reported deaths due to COVID-19 on January 1. This represents 612,000 additional deaths from October 11 to January 1. Daily reported deaths will decline to 6,800 by later November and then begin increasing again (Figure 22).

- Under our *reference scenario*, our model projects 13,016,000 cumulative total deaths due to COVID-19 on January 1. This represents 1,346,000 additional deaths from October 11 to January 1 (Figure 22).

- If *universal mask coverage (95%)* were attained in the next week, our model projects 200,000 fewer cumulative reported deaths compared to the reference scenario on January 1.

- Under our *worse scenario*, our model projects 6,543,000 cumulative reported deaths on January 1, an additional 650,000 deaths compared to our reference scenario. Daily reported deaths in the *worse scenario* will rise to nearly 30,000 by December 30, 2021 (Figure 22).

- Daily infections in the *reference scenario* will rise to 4.7 million by mid-December (Figure 23). Daily infections in the *worse scenario* will rise to 13.3 million by the first week of December 7 (Figure 23).

- Daily cases in the *reference scenario* will decline to 400,000 by the end of October 1 (Figure 24). Daily cases in the *worse scenario* will rise to 2.5 million by the third week of December (Figure 24).

- Daily hospital census in the *reference scenario* will decline to 526,190 by November 10, 2021 (Figure 25). Daily hospital census in the *worse scenario* will rise to 2,280,990 by December 26, 2021 (Figure 25).
Model updates

In this new release, we have introduced three major changes. First, we have very substantially updated the data and methods used to estimate excess mortality related to the pandemic. Second, we are now estimating the fraction of excess mortality in each country that is directly related to COVID-19 and the fraction that is increased mortality in individuals who were not PCR-positive at the time of death. Third, the estimation of past infection triangulating on cases, hospitalizations, deaths, and the infection-detection rate, infection-hospitalization rate, and infection-fatality rate has been revised to capture multiple sources of uncertainty. Below, we provide more detail on these revisions.

In addition to the methods changes, we have also made a change in the indicators we report. We now show in our tools and briefs reported and total COVID-19 deaths, while previously we were showing reported and excess.

1. Revisions to estimating excess mortality. For this analysis, countries can be divided into two groups: a) countries that have reported monthly or weekly deaths due to all causes before and during the pandemic, and b) countries that have not reported deaths during the pandemic. Most countries are in group b.

As previously described, we provide estimates of excess mortality for countries that report all-cause mortality data which are based on an ensemble of six different models. These six models are weighted by their root mean squared errors from an out-of-sample predictive validity test. As in our previous analysis, late registration is evaluated by comparing successive releases of weekly or monthly all-cause mortality data. The more recent weeks/months where reported all-cause mortality is less than 99% complete were excluded from our analysis. In addition, we also included provincial-level excess mortality rate estimates provided by the Medical Research Council of South Africa and excess mortality based on reported deaths in the civil registration system for periods during the first and second waves of COVID-19 from nine states in India. Inclusion of civil registration data for these states in India very substantially increases estimates of excess mortality for India, particularly during the Delta variant surge. In total, we have data for 163 countries and 220 states/provinces within countries.

To predict excess mortality for all locations without directly measured all-cause mortality, we evaluated the relationship between the excess mortality rate and a list of COVID-19-related covariates such as infection-detection rate and covariates suggested by meta-analysis conducted by the US Centers for Disease Control and Prevention. To arrive at a parsimonious model with covariates with sensible direction of effect on excess mortality rate, we run our model using Least Absolute Shrinkage and Selection Operator (LASSO) regression to help identify covariates to be included in our analysis. Through our model selection process, the list of covariates included are:

- Cumulative seroprevalence (lagged)
- Mobility (lagged)
- Infection-detection rate (lagged)
- Reported COVID-19 mortality rate
- Crude death rate
- Prevalence of diabetes
- Prevalence of smoking
- HIV death rate
- Inpatient admission rate
- Quality of death registration
- Average latitude
- Proportion of population over age 75
- Prevalence of hypertension
- Healthcare Access and Quality Index

To account for uncertainty in both directly estimated excess mortality based on registered deaths and the selected covariates, we run our estimation 100 times based on draw-level excess mortality and draw-level covariates. We use the draw-level residuals not explained by the fixed effects of the selected covariates in making predictions for locations with all-cause mortality to match the observed data. Regional and
super-region-level residuals are generated as the mean of locations included in those aggregated location hierarchies. Given the diverse and incomplete time period covered by the civil registration data from India, the average of state-level residuals is used for all states in India. We predict excess mortality from March 1, 2020, to September 26, 2021, using 100 draws of covariates for this cumulative period and the draw-level model coefficients and residuals estimated in the previous step. Figure 1 shows the estimated excess mortality rate (deaths per 100,000) for the aforementioned time period.

**Figure 1: Estimated excess mortality rate (deaths per 100,000) from March 1, 2020, to September 26, 2021**

2. *Estimating the fraction of excess mortality directly attributable to COVID-19 infection.* Estimating the deaths in individuals that occurred when actively infected with COVID-19 is challenging. Some jurisdictions within countries and some countries, such as the Russian Federation, have reported deaths where COVID-19 is reported on the death certificate as the underlying cause of death and, in addition, PCR-positive patients who have another cause of death listed as underlying cause on the death certificate. Following WHO recommendations, we define in principle total COVID-19 deaths as all deaths where the individual was actively infected at the time of death. The number of jurisdictions reporting this sort of detailed data, however, is very limited. We have had to use a statistical estimation approach to approximate the fraction of excess deaths that are total COVID-19 deaths. In particular, we use the regression analysis for excess mortality and compute a counterfactual level of excess mortality where the infection-detection rate is set to the observed maximum level and set mobility to the pre-COVID-19 baseline. These are meant to correct excess mortality for changes due to under-reporting and changes in behavior such as care-seeking related to mobility. In a given location, if reported COVID-19 deaths are higher than estimated total COVID-19 deaths, we use reported COVID-19 as the estimate of total COVID-19 deaths. Figure 2 shows the ratio of estimated total COVID-19 deaths to reported COVID-19 deaths by location.
3. We have improved how we estimate past COVID-19 infections to better reflect the various sources of uncertainty that impact that estimation process. This includes the following changes which were introduced in this week’s release:

a) We have implemented an ensemble model for our infection-fatality rate and infection-hospitalization rate models that uses the 100 most predictive combinations of the following covariates (in addition to time). These covariates were based on a US CDC meta-analysis of factors related to COVID-19 infection.

i. Obesity prevalence
ii. Cardiovascular disease prevalence
iii. Cancer prevalence
iv. Chronic kidney disease prevalence
v. Diabetes prevalence
vi. Chronic obstructive pulmonary disease prevalence
vii. Smoking prevalence
viii. Universal health care coverage
ix. Healthcare Access and Quality Index

b) We also used an ensemble model for infection-detection rate based on the following covariates (one used in each model, along with testing capacity):

i. Universal health care coverage
ii. Healthcare Access and Quality Index
iii. Proportion of the population 65 years and older

c) We generated 100 samples of each seroprevalence observation based on the reported error in seroprevalence studies, and then created bootstrapped samples from those 100 sets of seroprevalence data to include in each model in the ensemble.

d) When correcting seroprevalence studies for under-reporting due to seroreversion, we sampled curves from the assay-specific sensitivity decay functions based on the error reported in those studies rather than using the point estimates only.

e) Rather than assuming a single fixed value of cross-variant immunity at 0.5, we sampled from a uniform distribution ranging from 0.3 to 0.7 (as is already done in our Susceptible–Exposed–Infectious–Recovered [SEIR] model).
f) Rather than assuming a single fixed value of increased risk of hospitalization and mortality for non-ancestral variants relative to ancestral, we use an estimate found in the literature (https://www.bmj.com/content/372/bmj.n579) of 1.64 (95% CI: 1.32–2.04) – an increase from the previous source we drew from, which reported 1.29.

g) When triangulating infections based on cases, deaths, and hospitalizations, we give more weight to one of those three input series in each sub-model to better capture heterogeneity among these data.

Figure 6. Estimated percent of the population infected with COVID-19 on October 11, 2021

Figure 7. Mean effective R on September 30, 2021. Effective R less than 1 means that transmission should decline, all other things being held the same. The estimate of effective R is based on the combined analysis of deaths, case reporting, and hospitalizations where available. Current reported cases reflect infections 11-13 days prior, so estimates of effective R can only be made for the recent past.
Figure 8. Percent of COVID-19 infections detected. This is estimated as the ratio of reported daily COVID-19 cases to estimated daily COVID-19 infections based on the SEIR disease transmission model. Due to measurement errors in cases and testing rates, the infection-detection rate can exceed 100% at particular points in time.

Projections and scenarios

We produce three scenarios when projecting COVID-19. The reference scenario is our forecast of what we think is most likely to happen:

- Vaccines are distributed at the expected pace. Brand- and variant-specific vaccine efficacy is updated using the latest available information from peer-reviewed publications and other reports.
- Future mask use is the mean of mask use over the last 7 days.
- Mobility increases as vaccine coverage increases.
- Governments adapt their response by re-imposing social distancing mandates for 6 weeks whenever daily deaths reach 8 per million, unless a location has already spent at least 7 of the last 14 days with daily deaths above this rate, and not yet re-imposed social distancing mandates. In this case, the reference scenario assumes that mandates are re-imposed when daily deaths reach 15 per million.
- Variants Alpha, Beta, Gamma, and Delta continue to spread regionally and globally from locations with sufficient transmission.

The worse scenario modifies the reference scenario assumption in four ways:

- 100% of vaccinated individuals stop using masks.
- Mobility increases in all locations to 25% above the pre-pandemic winter baseline, irrespective of vaccine coverage.
- Governments are more reluctant to re-impose social distancing mandates, waiting until the daily death rate reaches 15 per million, unless a location has already spent at least 7 of the last 14 days with daily deaths above this rate, and not yet re-imposed social distancing mandates. In this case, the reference scenario assumes that mandates are re-imposed when daily deaths reach 38 per million. In either case, we assume social distancing mandates remain in effect for 6 weeks.
- Variants Alpha, Beta, Gamma, and Delta spread between locations twice as fast when compared with our reference scenario.

The universal masks scenario makes all the same assumptions as the reference scenario but assumes all locations reach 95% mask use within 7 days.

More information

Data sources:

Mask use and vaccine confidence data are from the The Delphi Group at Carnegie Mellon University and University of Maryland COVID-19 Trends and Impact Surveys, in partnership with Facebook. Mask use data are also from Premise, the Kaiser Family Foundation, and the YouGov COVID-19 Behaviour Tracker survey.

Genetic sequence and metadata are primarily from the GISAID Initiative. Further details available on the COVID-19 model FAQ page.

A note of thanks:

We wish to warmly acknowledge the support of these and others who have made our COVID-19 estimation efforts possible.
